More precisely: when its automorphism group is not a crystallographic space group.

*(Crystallographic nets and their quotient graphs,
W. E. Klee 2004.)*

A crystalline material. What might be its atomic structure?

Define $\alpha_\varphi: \mathbb{R}^n \rightarrow \mathbb{R}^n$ affine with $\alpha_\varphi(p(v_i)) = p(\varphi(v_i))$ for just enough vertices $v_i \in V(G)$ to make it unique.

If p and $p \circ \varphi$ are periodic, then $\alpha_\varphi \circ p = p \circ \varphi$ everywhere.

Because we have finitely many edge lattices, there can up to translations only be finitely many such α_φ .

By a standard trick (averaging the inner product), we can turn them all into rigid motions, a.k.a. isometries.

Thus $\varphi \mapsto \alpha_\varphi$ defines a group homomorphism that maps $\text{Aut}(G)$ onto a crystallographic group.

How could p be periodic, but not $p \circ \varphi$?

For an abstract graph G , we have to explicitly pick a translation group $T \leq \text{Aut}(G)$. If G is not crystallographic, T is not unique and we can have $\varphi T \varphi^{-1} \neq T$.

If we can show that α_φ can be defined on some vertex sublattice with respect to T , everything is good.

How can we exclude rogue automorphisms that mess up all the sublattices, no matter how large?
